Errata to the pre-analysis plan: #ManyDaughters

Maria Polipciuc*

Things I would have done differently in the pre-registration...

1. Had I seen the data

- If I had known that some outcome variables (those on the position of women in society, for H1 and H4) were measured in repeated cross-sections rather than in panel format, I would not have used panel data specifications (the `xt` family in Stata) with individual fixed effects and errors clustered at the individual level.
- I would have added weights (it was not clear to me that we would have access to them).
- I would have removed the control variable "disability status" from the specifications for H1 and H4, as the question either (i) was not asked in the years when the outcome variables for H1 / H4 were collected or (ii) was not asked of the subsample of individuals who were asked about the position of women in society.
- I would have specified age as being calculated using the variable `syear` instead of `pgpiyear`, since `pgpiyear` was only recorded in some years.
- For years of education, I would have used `pgbilzeit` instead of `pgbilzt`, as the latter variable was not in SOEP Core but in SOEP IS.
- For living in East/West Germany, I would have used `sampreg` instead of `bgsampreg`, as this was the correct variable in SOEP Core.

2. Had I spent more time catching my own errors

- I would not have written an impossible specification for H2: `xtlogit` with fixed effects. In the analysis, I used `xtreg` with individual fixed effects and standard errors clustered at the individual level, even though the outcome variable was binary ("Has voted for AfD" in 2014, 2018). I did this because, on the 5% of the data available, `xtlogit` without fixed effects did not converge. I made this decision before seeing results in the full sample, as `xtlogit` relies on switchers in the dependent variable for identification, and I did not expect many even in the full sample. The OLS regression should provide an acceptable approximation.

- I would not have included a variable that does not vary within individuals in a fixed-effects model ("migration background" in regressions using panel data with FEs, such as those for H2 and H3).

- For H3: The hypothesis test differs slightly because I had made a mistake in specifying that the mean of the dependent variable in the non-treated sample was α_i (the constant in the regression). This is incorrect because the preregistered model uses individual fixed effects. In the analysis, I instead calculated the mean share of leisure time for men in heterosexual couples living in the same household who are or become fathers of at least one daughter during their time in the panel, measured before having an (additional) daughter. I then tested whether the distance from an egalitarian split in leisure time (0.5) changed after the birth of a daughter. Specifically, I compared the absolute difference between the pre-daughter mean and 0.5 with the absolute difference between the expected post-daughter mean (the pre-daughter mean plus the coefficient β_1) and 0.5. This comparison was implemented using `nlcom`, which tests nonlinear combinations of coefficients; its use was necessary because the test involved absolute values.

3. Omissions

- I would have added "age" as a control variable in all regressions, not just "age squared."

- I forgot to specify the baseline for the NUTS region; I used Berlin.

- I would have restricted the estimation sample to individuals in private households, for whom `pop` is 1 or 2.
