Comments on our Pre-Analysis Plan

The scope of our pre-analysis plan (PAP) was defined by our understanding of the task. Specifically, our PAP only contains four regression models, i.e., one per hypothesis, as requested. As such, this PAP does not reflect the depth of analysis that would be required for an academic paper. It does not specify any ways to assess testable assumptions or the robustness of the analysis. Similar to a PAP we would write for a paper, our PAP does not justify our choices. This would be part of the "data" or "identification" section of the paper, and for this project, we understood the focus to be on the analysis, not its justification.

The following document clarifies our assumptions and explains our choices.

1. **Choice of "at least one daughter" (as compared to only sons) as the independent variable.** In the German context, it is reasonable to assume that the sex of the child is random, conditional on having a child. We hence focus our analysis on parents with at least one child. The decision to have more than one child, however, may depend on the sex of the first child. This is why we i) control for the total number of children and ii) do not use the number of daughters as the independent variable. In our opinion, this approach strikes a balance between concerns regarding internal and external validity. The latter would be more pronounced if we chose to focus our analysis on parents with only one child. Our analysis estimates extensive margin effects for all parents.

2. **Measurement of gender-egalitarian attitudes**. Although variables plj0620, plj0624, and plj0625 arguably measure gender-egalitarian attitudes more precisely, these items are available only for a subsample of respondents with a migration background. Using them would therefore result in a substantially reduced and selected sample. To maintain broader representativeness and avoid restricting our analysis to this subsample, we opted for the plh variables (plh0298, plh0302, plh0308), which are, to our knowledge, available for the full SOEP sample without such limitations.

3. **Measurement of left-leaning political attitudes**. Self-reported left–right placement on a political spectrum (e.g., on an 11-point Likert scale) could potentially lead to problems regarding interpersonal comparability: two individuals who report adjacent but not the same positions may vote for the same political party, or a person who classifies themselves as "left-leaning" may vote for a party that is objectively more right-leaning. To mitigate such interpretational ambiguities, we rely on reported voting behavior as an indicator

of political preferences. In the analysis, we control for the survey year to capture general shifts in the political landscape over time. The downside of reported voting behavior is that shifts in individual behavior may be harder to detect among those who vote for a specific party out of habit rather than because of their current political views. Weighing the pros and cons, we believe that stated voting behavior is a relevant approximation of political attitudes.

4. **Measurement of gender equality in the household**. We chose to focus on unpaid labor, as this can be adjusted more easily than paid labor (due to less path-dependency and fewer external constraints). Consistent with the wording of hypothesis H3, we conduct the analysis at the household level (with one observation per couple per year). By constructing the dependent variable as the share of total unpaid labor hours performed by the female partner, we capture changes in relative rather than absolute gender differences or the absolute workload of the female partner. We believe that the relative gender difference in unpaid labor is preferable in a context like Germany, where regional and local heterogeneity exists in, e.g., access to child care (which cannot be fully captured by our West-Germany dummy).

   Note of correction: Although our Stata script correctly incorporates all relevant items measuring time spent on housework, repairs, and childcare throughout the week (and the PAP lists these items), the presentation within the corresponding table of the PAP is slightly misleading. Specifically, certain variables (e.g., plh0012) are misclassified in the table as representing weekday housework hours, whereas they in fact capture housework on Saturdays. We apologize for this mistake.
