Comments on our decisions and changes in the PAP for #ManyD

- We decided to not just focus on the sex of the first child but to include **all children** that the respondents have by the time of the survey year. The aim was to test the hypotheses on the effects of having daughters. This should be substantially different from the effects of having the first child as a daughter, which is not the objective of the project. In the context of Germany, where sex selection of the child is prohibited, the sex of further children should not be dependent on the sex of the first child and should not be affected by gender attitudes. For individuals of Turkish origin, who takes up a majority of individuals with a migration background in Germany (less than 4 per cent of the total population) and tend to show a preference of sons over daughters, there is, to our knowledge, no empirical evidence demonstrating the sex selection of the children. Therefore, we ruled out the possibility of selection bias when focusing on all of the respondents' children, instead of studying solely the first child. Also, we include migration background as a control. Furthermore, we built the independent variable with three categories: 'No daughter', 'Only daughter(s), and 'Mixed' (having at least one daughter and one son). This measure is more informative, aiming to test the potential differences in the effects of having only daughters and having sons additionally.

- To test H1 and H4, we initially included three different items to measure support for gender equality and treated them as three dependent variables separately: 1) Children below the age of 6 suffer if their mother works; 2) Children below the age of 3 suffer if their mother works; 3) Best if man and woman work the same amount so they can share the responsibility. Since we could only keep one dependent variable, we decided to **build an index** out of these items but had to **drop the third item** as it is not strongly correlated with the other two. In the end, we built an index out of the first two items.

- We initially planned to run both random effects and fixed effects models for testing H2 and H3. As we could only keep one type of models, we finally opted to **random effects models for H2** because we only have 4 years/waves (2005, 2009, 2014, 2019) due to the availability of the dependent variable on left-leaning political preferences. This would result in less variation over time, particularly with regard to political preferences, which tend to remain relatively stable over time. In contrast, we decided to run **fixed effects models for H3** because the dependent variable (gender equality behaviour in the household) is available in each year from 2000 to 2020, with potentially larger variation over time. We were able to analyse the extent to which changes in the behaviour could be influenced by changes in the sex composition of the children.
