As we have described all the explanations in the coding, this file is just a short overview of all the hypotheses:

HYPOTHESIS H_1

Our model would test whether the the proxy identified in some of the studies (provided as example) would be deteremined by the controlled by the selected household and family characterstics, especially by the especially, income, age, education, nationality (and origin) and marital status. We also control for the survey year. The perfect dependent variable would be according to our search of the prior literature and SOEP data variable from the plh set of data (https://paneldata.org/soep-core/datasets/bjp/bjp_166_04) plh0395i01, plh0395i02, plh0395i03, plh0395i04, plh0395i05, plh0395i06, especially "Sex assignment is not so important for a person's development", which we do not have available - and we do not know why. Alternatively, it would make sense to use of the proxy variables from Educational Goals (edgoal) set of variables (https://paneldata.org/soep-core/topics?open=topic_edg), specifically from the qualities and abilities, such as "behaves like a normal girl/boy, works toward achieving his/her goals and others. However, again, this set of variables is not available in the dataset we got, so we cannot make use of those. Therefore, we have to assume that having a job that requires hard manual labour (plb0085) is a good measure of support for gender equality (hypothesis 1), if having a job with less manual labour, the respondent is more likely to support gender equality. Accordingly, we run a linear OLS regression analysis with plb0085 as dependent variable and the dummy variable d_daughter as independent variable .

HYPOTHESIS H_2

As seen from the described variables, our model aims to test whether having daughters is more likely associated with a left-wing way of voting behaviour. The analysis is moderated by the control variables and the general interest in politics. The dependent variable is binary, meaning that the model aims to test whether the respondents with daughters are more likely to vote for the selected left-wing parties or not.

HYPOTHESIS H_3

As seen from the described variables, our model aims to test whether the household homework, approximated as the proportion of hours spent on childcare and homework, is more equally distributed in families with daughters. The distribution of the work at the household is constructed for each of the partners, and then the percentage of the total domestic work is calculated, serving as a dependent variable. The daughter variable is then being used as the key independent variable. Given the nature of the dependent variable, we can this time opt for simple OLS regression with household and family controls.

HYPOTHESIS H_4

Similarly as in H1, our model would test whether the the proxy identified in some of the studies (provided as example) would be deteremined by the controlled by the selected household and family charactersitics, especially by the especially, income, age, education, nationality (and origin) and marital status. We also control for the survey year. The perfect dependent variable would be according to our search of the prior literature and SOEP data variable from the plh set of data (https://paneldata.org/soep-core/datasets/bjp/bjp_166_04) plh0395i01, plh0395i02, plh0395i03, plh0395i04, plh0395i05, plh0395i06, especially "Sex assignment is not so important for a person's development", which we do not have available - and we do not know why. Alternatively, it would make sense to use of the proxy variables from Educational Goals (edgoal) set of variables (https://paneldata.org/soep-core/topics?open=topic_edg), specifically from the qualities and abilities, such as "behaves like a normal girl / boy, works toward achieving his/her goals and others. However, again this set of variables is not available in the dataset we got, so we cannot make use of those. The hypothesis is test via the interaction effects of the Difference in Differences Approach (Dahl, G. B., & Moretti, E. (2008). The demand for sons. The review of economic studies, 75(4), 1085-1120.). The key variable here is thus the interaction term introduced before: interaction_F_D variable. Therefore, we have have to assume that having a job that requires hard manual labor (plb0085) is a good measure of support for gender equality (hypothesis 1), if having a job with less manual labor, the respondent is more likely to support gender equality. Accordingly, we run a linear OLS regression analysis with plb0085 as dependent variable and the dummy variable d_daughter as independent variable *
