H1. Having daughters leads to stronger support for gender equality (as measured by attitudes).
That is, denoting X as a measure of support for gender equality,
(X for respondents with daughters) > (X for respondents without daughters).

Variables: Which variables will you include? How will these variables be coded— will you use them the way they are or recode them, and if so, how?

- Our dependent variables, support for gender equality, is measured by a constructed index based on the SOEP variables *plj0621, plj0622, plj0623, plj0624,* and *plj0625*. These variables are surveyed in the year 2016, 2017 and 2018 and captures answers to the following questions:
    - Do you agree with the following statements?
        - plj0621: Having a job is the best way for a woman to be independent.
        - plj0622: Even a married woman should have a paid job so that she can be financially independent.
        - plj0623: If a woman earns more money than her partner, this inevitably leads to problems.
        - plj0624: For parents, vocational training or higher education for their sons should be more important than vocational training or higher education for their daughters.
        - plj0625: At home, the husband should have the final say.

  For *plj0621* and *plj0621*, we assume that higher values are associated with larger support for gender equality. For *plj0623, plj0624,* and *plj0625,* we assume that lower values are associated with larger support for gender equality, so we reverse the scale for these variables by recoding 1 to 7, 2 to 6, and so on. Our index is the mean across the 5 variables (the latter three with the reversed scaling).
- Our main treatment variable is having at least one daughter in the survey year (*syear*) based on the SOEP variables *kidsex01, kidsex02, …, kidsex19* and *kidgeb01, …, kidgeb19* for up to 19 children per observation. The treatment variable has the value 1 if at least one kid is female and is born in or before the survey year.
- We control for the number of children that one individual has before up until the survey year, using number-of-children fixed effects. To not include too many controls, we only consider 6 distinct variables: having no children, having 1 child, having 2 children, having 3 children, having 4 children, and having 5 children or more (born in or before the year of the survey). The variable builds on *kidgeb01, …, kidgeb19* and *syear*.
- We also control for the age of the observation in the survey year using the SOEP variables *syear* and *gebjahr*.

Inclusion/exclusion criteria: Are there any observations you will exclude? If yes, which? Which years will you include/what period will you study?

- We only consider observations with non-missing values on the abovementioned variables. This effectively excludes all survey years but 2016-18.
- We furthermore only consider private households.
- We only consider individuals that provided non-improbable information on the birthyear of all their children.

Exact analysis: Please write down the exact specification of the regression model, including the names of the dependent and independent variables, and whether you use robust standard errors or something else.

- We regress our gender attitude index on whether a participant (i) has any daughter controlling for number-of-children fixed effects and age. Standard errors are clustered on the household level (h):

$$gender\ att\ index_{ih} = \beta_o + \beta_1 * any\ daughter_{ih} + \sum_{k=1}^{5} \gamma_k * (sumkids\ capped_{ih} = k) + \beta_2 *\ age_{ih} + \varepsilon_{ih}$$

Interpretation of results: Please specify which statistic you will take into account for testing the hypothesis. How do you interpret whether your test result is in line with the hypothesis or not?

- We will consider the clustered standard errors and the resulting p-values of the OLS regression.
- We consider p-values of below 0.05 as significant.
- If the coefficient β_1 is positive and the associated p-value is below 0.05, we take this as evidence that the results are in line with our hypothesis.
- If the p-value associated with β_1 is 0.05 or above, we do not find evidence in favor of our hypothesis.
- If the coefficient β_1 is negative and the associated p-value is below 0.05, we take this as evidence that the results are contrary to hypothesis and that having daughters leads to weaker support for gender equality.

H2. Having daughters leads to more left-leaning political preferences.

That is, denoting Y as a measure of left-leaning political preferences,
(Y for respondents with daughters) > (Y for respondents without daughters).

Variables:

- Our dependent variable, i.e. left-leaning political preferences, is a newly constructed variable based on the SOEP variables *plh0004*. This variable (*plh0004*) is surveyed in the years 2005, 2009, 2014, and 2019 and capture answers to the following question: **In politics, people often talk about "left" and "right" when describing different political views. When you think about your own political view, how would you rate them on the scale below?** - How would you rate your political views?
- We recode the variable, so that larger values indicate more left-leaning political preferences.
- Our main treatment variable is having at least one daughter in the survey year (*syear*) based on the SOEP variables *kidsex01, kidsex02, …, kidsex19* and *kidgeb01, …, kidgeb19* for up to 19 children per observation. The treatment variable has the value 1 if at least one kid is female and is born in or before the survey year.
- We control for the number of children that one respondent has before up until the survey year, using number-of-children fixed effects. To not include too many controls, we only consider 6 distinct variables: having no children, having 1 child, having 2 children, having 3 children, having 4 children, and having 5 children or more (born in or before the year of the survey). The variable builds on *kidgeb01, …, kidgeb19* and *syear*.

Inclusion/exclusion criteria: …

- We only consider observations with non-missing values on the abovementioned variables. This effectively excludes all survey years but 2005, 2009, 2014, and 2019.
- We furthermore only consider private households.
- We only consider individuals that provided non-improbable information on the birthyear of all their children.

Exact analysis:

- Heterogeneity robuts DiD model, following Chaisemartin and D'Haultfoeuille (2024), for a case with staggered and binary treatment. We regress attitudes towards left-leaning political views in a given year on whether a parent has any daughter born before attitudes are surveyed.

- Controlling for number-of-children-fixed-effects, and clustering standard errors on the level of the treatment (the household)
- No multiple event study effects are estimated because (i) only four periods and (ii) periods are 4-5 years apart already

Interpretation of results: …

- We will consider the clustered standard errors and the resulting p-values of the regression.
- We consider p-values of below 0.05 as significant.
- If the coefficient is positive and the associated p-value is below 0.05, we take this as evidence that the results are in line with our hypothesis.
- If the p-value associated with is 0.05 or above, we do not find evidence in favor of our hypothesis.
- If the coefficient is negative and the associated p-value is below 0.05, we take this as evidence that the results are contrary to hypothesis and that having daughters leads to less left-leaning political preferences.

H3. Having daughters leads to more gender equality in the household (as measured by behaviors or outcomes).

That is, denoting Z as a measure of gender equality in the household,
(Z for respondents with daughters) > (Z for respondents without daughters).

Variables:

- Our dependent variable is the share of time spent on housework done by a men in a partnership, during a typical weekday. We use the variable pli0043_h to construct this variable. The corresponding question is "What is a typical day like for you? How many hours do you spend on the following activities on a typical weekday: housework (washing, cleaning, cooking…)". We calculate our outcome by tracking the number of hours of housework done by both the male and the female partner, and we then compute the male share. Our variable is included in every survey year in our sample, ie. for each year between 2000 and 2020. Our dependent variable then takes a value comprised between 0 if the male partner doesn't do housework at all (in a typical weekday), and 1 if the male partner does all the housework in the household.

- Our main treatment variable is having at least one daughter in the survey year (*syear*) based on the SOEP variables *kidsex01, kidsex02, …, kidsex19* and *kidgeb01, …, kidgeb19* for up to 19 children per observation. The treatment variable has the value 1 if at least one kid is female and is born in or before the survey year.

- We control for the number of children that one respondent has before up until the survey year, using number-of-children fixed effects. To not include too many controls, we only consider 6 distinct variables: having no children, having 1 child, having 2 children, having 3 children, having 4 children, and having 5 children or more (born in or before the year of the survey). The variable builds on *kidgeb01, …, kidgeb19* and *syear*.

Inclusion/exclusion criteria: …

- We only consider private households.
- We only consider individuals that provided non-improbable information on the birthyear of all their children.
- We only keep participants with stable partners over time in the SOEP: it means that if an individual has no partner in the SOEP at some point, or that if he changes partner at one point during his survey years in the SOEP, we exclude him from the analysis.
- We only keep heterosexual partners, ie. with one male and one female, as we want to look at the effect of having a daughter on gender equity.

- We look at the partnership where partners do at least some housework.

Exact analysis:

- Heterogeneity robuts DiD model, following Chaisemartin and D'Haultfoeuille (2024), for a case with staggered and binary treatment. We regress the share of housework done by the male partner of the household in a given year on whether a parent has any daughter born before the outcome is surveyed. Specifically, the model compares the share of weekday household labor done by men before and after they have a daughter, relative to others who have not yet had a daughter.
- Controlling for number-of-children-fixed-effects.
- Restricting the sample to people that have kids in the syear t, so that our control group include parents with children, but without daughters.
- 4 multiple event studies effects are estimated. Total average effect is considered.

Interpretation of results: …

- We will consider the standard error and the resulting p-values of the regression.
- We consider p-values of below 0.05 as significant.
- If the coefficient of the total average effect is positive and the associated p-value is below 0.05, we take this as evidence that the results are in line with our hypothesis.
- If the p-value associated with is 0.05 or above, we do not find evidence in favor of our hypothesis.
- If the coefficient is negative and the associated p-value is below 0.05, we take this as evidence that the results are contrary to hypothesis and that having daughters leads to weaker support for gender equality.

H4. Having daughters leads to a larger increase in the support of gender equality for men than for women (with gender equality measured by attitudes).

That is, denoting X as a measure of support for gender equality,
X for male respondents with daughters − X for male respondents without daughters >
X for female respondents with daughters − X for female respondents without daughters!

Variables:

- Our dependent variables, support for gender equality, is measured by a constructed index based on the SOEP variables *plj0621, plj0622, plj0623, plj0624,* and *plj0625*. These variables are surveyed in the year 2016, 2017 and 2018 and captures answers to the following questions:
    - Do you agree with the following statements ?
        - plj0621: Having a job is the best way for a woman to be independent.
        - plj0622: Even a married woman should have a paid job so that she can be financially independent.
        - plj0623: If a woman earns more money than her partner, this inevitably leads to problems.
        - plj0624: For parents, vocational training or higher education for their sons should be more important than vocational training or higher education for their daughters.
        - plj0625: At home, the husband should have the final say.

  For *plj0621* and *plj0621*, we assume that higher values are associated with larger support for gender equality. For *plj0623, plj0624,* and *plj0625,* we assume that lower values are associated with larger support for gender equality, so we reverse the scale for these variables by recoding 1 to 7, 2 to 6, and so on. Our index is the mean across the 5 variables (the latter three with the reversed scaling).

- Our main treatment variable is an interaction term of being a male and having a daughter. It then turns to one if a parent is a male and have a female kid. The first term of the interaction is the male variable (sex), it takes the value 1 if the individual is a male. The second term corresponds to having at least one daughter in the survey year (*syear*) based on the SOEP variables *kidsex01, kidsex02, …, kidsex19* and *kidgeb01, …, kidgeb19* for up to 19 children per observation. This variable has the value 1 if at least one kid is female and is born in or before the survey year.

- We control for the number of children that one individual has before up until the survey year, using number-of-children fixed effects. To not include too many controls, we only consider 6 distinct variables: having no children, having 1 child, having 2 children, having 3 children, having 4 children, and having 5 children or more (born in

or before the year of the survey). The variable builds on *kidgeb01, …, kidgeb19* and *syear*.

- We also control for the age of the observation in the survey year using the SOEP variables *syear* and *gebjahr*.

Inclusion/exclusion criteria: Are there any observations you will exclude? If yes, which? Which years will you include/what period will you study?

- We only consider observations with non-missing values on the abovementioned variables. This effectively excludes all survey years but 2016-18.
- We furthermore only consider private households.
- We only consider individuals that provided non-improbable information on the birthyear of all their children.

Exact analysis: Please write down the exact specification of the regression model, including the names of the dependent and independent variables, and whether you use robust standard errors or something else.

- We regress our gender attitude index on whether a participant (i) is parent that has any daughter born before attitude are surveyed interacted with a dummy indicating whether the respondent is a male, controlling for number-of-children fixed effects and age. Standard errors are clustered on the household level (h):

$$gender\ att_{index_{ih}} = \beta_0 + \beta_1 * any_{daughter_{ih}} + \beta 2 * male_{ih} + \beta 3 * (any_{daughter_{ih}} \times male_{ih}) + \sum_{k=1}^{5} \gamma_k * (sumkids\ capped_{ih} = k) + \beta 4 \cdot age_{ih} + \varepsilon_{ih}$$

Interpretation of results: Please specify which statistic you will take into account for testing the hypothesis. How do you interpret whether your test result is in line with the hypothesis or not?

- We will consider the clustered standard errors and the resulting p-values of the OLS regression.
- We consider p-values of below 0.05 as significant.
- If the coefficient β_3 is positive and the associated p-value is below 0.05, we take this as evidence that the results are in line with our hypothesis, ie. that male with daughters knows a greater effect of having a daughter than female, on their attitudes towards gender equity.
- If the p-value associated with β_3 is 0.05 or above, we do not find evidence in favor of our hypothesis.

- If the coefficient β_3 is negative and the associated p-value is below 0.05, we take this as evidence that the results are contrary to hypothesis and that having daughters leads to weaker support among men than women for gender equality.
